

Homework 4

CS/ECE 374B

Due 8 p.m. on Tuesday, October 6

All of this has happened before and all this will happen again.

1. Solve the following recurrences. For parts (a) and (b), give an *exact* solution. For parts (c) and (d), give an asymptotic one. In both cases, justify your solution.

(2) (a) $A(n) = A(n-1) + 2n - 1; A(0) = 0$

Solution:

We will do this problem by unrolling:

$$A(n) = A(n-1) + 2n - 1$$

$$A(n) = (A(n-2) + 2(n-1) - 1) + 2n - 1$$

$$A(n) = ((A(n-3) + 2(n-2) - 1) + 2(n-1) - 1) + 2n - 1$$

$$A(n) = A(n-3) + 6n - 9$$

\vdots

$$A(n) = A(n-k) + 2nk - k^2$$

$$A(n) = A(n-k) + k(2n-k)$$

The base case is $A(0) = 0$, so $n-k = 0$, and $k = n$ at base case. Plugging in...

$$A(n) = A(0) + n(2n-n)$$

$$A(n) = 0 + 2n^2 - n^2$$

$$A(n) = n^2$$

(3) (b) $B(n) = B(n-1) + \binom{n}{2}; B(0) = 0$

Solution:

We will do this problem by unrolling:

$$B(n) = B(n-1) + \binom{n}{2}$$

$$B(n) = B(n-2) + \binom{n-1}{2} + \binom{n}{2}$$

$$B(n) = B(n-3) + \binom{n-2}{2} + \binom{n-1}{2} + \binom{n}{2}$$

\vdots

$$B(n) = B(n-k) + \sum_{i=0}^k \binom{n-i}{2}$$

The base case is $B(0) = 0$, so $n-k = 0$, and $k = n$ at base case. Plugging in...

$$B(n) = B(0) + \frac{1}{6}n(n^2 - 1)$$

$$B(n) = 0 + \frac{1}{6}(n^3 - n)$$

$$B(n) = \frac{n^3 - n}{6}$$

(2) (c) $C(n) = C(n/2) + C(n/3) + C(n/6) + n$

Solution:

We will do this problem by recursion trees:

We model this recurrence as a recursion tree. the root node represents the base case, with a value of n . It has 3 nodes, with values $\frac{n}{2}, \frac{n}{3}, \frac{n}{6}$. The next level has 9 nodes, with values $\frac{n}{4}, \frac{n}{6}, \frac{n}{12}, \frac{n}{6}, \frac{n}{9}, \frac{n}{18}, \frac{n}{12}, \frac{n}{18}$,

$\frac{n}{36}$. We can see that the nodes at each level sum to n . Using the base case $C(\frac{n}{2^k}) = 1$, we see that the maximum depth of the tree is $k = \log n$. Therefore, we have $\log n$ levels with n work per level, so the recurrence is $\Theta(n \log n)$.

(3) (d) $D(n) = D(n/2) + D(n/3) + D(n/6) + n^2$

Solution:

We will do this problem by recursion trees:

We model this recurrence as a recursion tree. the root node represents the base case, with a value of n^2 . It has 3 nodes, with values $\frac{n^2}{4}, \frac{n^2}{9}, \frac{n^2}{36}$. The next level has 9 nodes, with values $\frac{n^2}{16}, \frac{n^2}{36}, \frac{n^2}{144}, \frac{n^2}{36}, \frac{n^2}{81}, \frac{n^2}{324}, \frac{n^2}{144}, \frac{n^2}{324}, \frac{n^2}{1296}$. We can see that the nodes at each level sum to $n^2(\frac{7n}{18})^i$. Since the sum per level is a decreasing geometric series, the overall recurrence is dominated by the root node of n^2 . Therefore the recurrence is $\Theta(n^2)$.

2. In class, we discussed the recursive algorithm for the Towers of Hanoi problem.

```
def hanoi(ndisks, source, dest, tmp):
    """ Move 'ndisks' from the 'source' tower to the 'dest' tower,
    using the 'tmp' tower as temporary space """
    if ndisks > 0:
        # recursively move stack of ndisks-1 disks to tmp tower
        hanoi(ndisks-1, source, tmp, dest)
        # move one disk from source to destination
        moveone(source, dest)
        # recursively move stack of ndisks-1 disks to dest tower
        hanoi(ndisks-1, tmp, dest, source)
    else:
        pass # do nothing
```

In the following, assume that the towers are numbered 0, 1, 2 and the standard task is to move n disks from tower 0 to tower 1 (i.e., $\text{hanoi}(n,0,1,2)$)

- (5) (a) Suppose that `moveone` had a restriction that either the source or the destination must be tower 0. Modify the recursive algorithm to abide by this restriction. Analyze *exactly* how many calls to `moveone` are needed to move n disks in your solution.

Solution: As before, our solution recursively moves $n - 1$ disks to the temporary tower, then moves the remaining disk to the destination, and moves the $n - 1$ disks to the destination. However, to avoid making an illegal calls, when it needs to make a recursive move between towers 1 and 2, it instead uses two moves, using tower 0 as an intermediate. As a result, every call to `moveone` is made with either source or destination being tower 0.

```
def hanoi(n, s, d, t):
    if n == 0:
        return
    if 0 in (s,t):
        # can move disks directly
        hanoi(n-1, s, t, d)
    else:
        # need indirect moves
        hanoi(n-1, s, d, t)
        hanoi(n-1, d, t, s)
    moveone(s, d)
    if 0 in (t,d):
        hanoi(n-1, t, d, s)
    else:
        hanoi(n-1, t, s, d)
        hanoi(n-1, s, d, t)
```

To analyze this, note that for all possible combination of (s, d, t) parameters— $(0,1,2)$, $(0,2,1)$, $(1,0,2)$, and $(2,0,1)$ —there are exactly 3 recursive calls made (except for the base case). This leaves us with the recurrence:

$$T(0) = 0$$
$$T(n) = 3T(n-1) + 1$$

The solution to the recurrence can be seen to be:

$$T(n) = \frac{3^n - 1}{2}$$

Indeed, assuming that $T(n-1) = \frac{3^{n-1}-1}{2}$, we have:

$$T(n) = 3T(n-1) + 1 = 3 \frac{3^{n-1}-1}{2} + 1 = \frac{3^n - 3}{2} + \frac{2}{2} = \frac{3^n - 1}{2}$$

■

- (5) (b) Suppose instead that you are give another call, `moveall` that can move an entire stack of disks from one tower to another, but `moveall` can only be called to move disks *from* tower 2. I.e., you may call `moveall(2,0)` or `moveall(2,1)`, using it with any other arguments will cause an error.

Modify the algorithm to take advantage of `moveall`. Calculate the exact number of calls to `moveone` and `moveall` your algorithm makes for n disks.

Solution: We can modify the standard Hanoi solution to make use of the `moveall` call whenever the source tower is tower 2. However, we have to be careful, since when we are in a recursive call, there could be other disks on tower 2 that we are not (yet) supposed to move. To account for this, we add an extra flag when we move a disk to tower 2 and then make a recursive call, to make sure we don't use `moveall` in that scenario.

```
def hanoi(ndisks, src, dst, tmp, twobusy=False):
    """ Move 'ndisks' from the 'src' tower to the 'dst' tower,
        using the 'tmp' tower as temporary space. 'twobusy'
        indicates whether tower 2 has other disks on it that
        we are not supposed to move. """
    if n == 0:
        return
    if s == 2 and not twobusy:
        # can move disks directly
        moveall(source, dest)
    else:
        hanoi(ndisks-1, src, tmp, dst, twobusy)
        moveone(src, dst)
        hanoi(ndisks-1, tmp, dst, src, twobusy or dst == 2)
```

To analyze the number of calls, we unroll the recursion a few steps. When we call `hanoi(n,0,1,2,False)`, it will make the following calls:

- `hanoi(n-1,0,2,1,False)`
- `moveone(0,1)`
- `hanoi(n-1,2,1,0,False)`

Expanding the next two recursive calls, we are left with:

- *Expansion of `hanoi(n-1,0,2,1,False)`*
 - `hanoi(n-2,0,1,2,False)`
 - `moveone(0,2)`
 - `hanoi(n-2,1,2,0,True)`
- `moveone(0,1)`
- *Expansion of `hanoi(n-1,2,1,0,False)`*
 - `moveall(2,1)`

Observe that if `twobusy` is `True`, our modified Hanoi function behaves exactly as the original one. Therefore, `hanoi(n-2,1,2,0,True)` will make exactly $2^{n-2} - 1$ calls to `moveone` and 0 calls to `moveall`.

Therefore, if we let $T(n)$ be the number of calls to `moveone` that `hanoi(n,0,1,2,False)` makes, we have the following recurrence:

$$T(n) = T(n-2) + 2^{n-2} - 1 + 2$$

For easier analysis, we can rewrite this as two recurrences:

$$T_{\text{even}}(n) = T(2n)$$

$$T_{\text{odd}}(n) = T(2n + 1)$$

Then:

$$T_{\text{even}}(n) = T_{\text{even}}(n - 1) + 2^{2n-2} + 1$$

$$T_{\text{odd}}(n) = T_{\text{odd}}(n - 1) + 2^{2n-1} + 1$$

Noting that $T_{\text{even}}(0) = 0$ and $T_{\text{odd}}(0) = 1$, we can solve these to obtain:

$$T_{\text{even}}(n) = n + \frac{2^{2n} - 1}{3}$$

$$T_{\text{odd}}(n) = n + \frac{2^{2n+1} + 1}{3}$$

We can combine these to obtain:

$$T(n) = \lfloor n/2 \rfloor + \frac{2^n + (-1)^{n+1}}{3}$$

Similarly, if we let $T'(n)$ be the number of calls to moveall, we can see that

$$T'(n) = T'(n - 2) + 1$$

With $T'(0) = T'(1) = 0$, we can solve this to obtain

$$T'(n) = \lfloor n/2 \rfloor$$

■

- (3) 3. (a) Suppose you have a string of n Christmas lights, numbered $1, \dots, n$ that are wired in series. One of the lights is broken and you want to find out which. You have a multimeter that you can use to test whether any section of the string works. I.e., $\text{test}(i, j)$ returns True if lights i through j (inclusive) are all working, and False if one of them is broken. Design a recursive algorithm to identify the broken light (you should assume there is exactly one) and analyze its runtime. For full credit your algorithm should make a sublinear number of calls to test (i.e., $o(n)$).

Solution:

```
def identifyBrokenLight(a,b):
    """ The top-level invocation is identifyBrokenLight(1,n). """
    if(a == b and test(a,a) == False): # identified broken light
        return a
    elif(a == b and test(a,b) == True): # no broken lights
        return -1
    elif(test(a,(a+b)/2) == False): # left half
        return identifyBrokenLight(a,(a+b)/2)
    elif(test((a+b)/2+1,b) == False): # right half
        return identifyBrokenLight((a+b)/2+1,b)
```

Every call to `identifyBrokenLight` halves the length of the string being examined, in a manner quite similar to binary search, so that finding the broken light takes $\Theta(\log n)$ time. ■

- (3) (b) Suppose now that up to k lights may be broken. Modify your algorithm to find all the broken lights. How big can k be before your algorithm is no longer faster than testing each light?

Solution:

```
def identifyBrokenLights(a,b):
    """ The top-level invocation is identifyBrokenLights(1,n). """
    found_lights = []
    if(a==b and test(a,a) == False): # found a broken light
        found_lights += a
    elif(test(a,b) == True): # no broken lights
        return found_lights
    elif(test(a,(a+b)/2) == False): # left half
        found_lights += identifyBrokenLights(a,(a+b)/2)
    elif(test((a+b)/2+1,b) == False): # right half
        found_lights += identifyBrokenLights((a+b)/2+1,b)
    return found_lights
```

This algorithm requires at most $\Theta(\log n)$ for each light, resulting in a total $\Theta(k \log n)$ runtime, making it no faster than brute force if $k = \frac{n}{\log n}$. ■

- (4) (c) In cryptography, an RSA key is the product of two large primes, $n = pq$. Each key n_i should use its own, randomly generated primes p_i and q_i ; however, due to flaws in random number generators occasionally two keys will share one or both factors.¹ For any two correctly generated keys, $\text{gcd}(n_i, n_j) = 1$, but if keys share a factor then $\text{gcd}(n_i, n_j) \neq 1$.

You are given a large collection of t keys, n_1, \dots, n_t and want to find out whether any of them share a factor. Since GCD takes time to compute, you can use a batch approach to speed up your computation. `batchgcd(i, j, k, l)` computes the GCD of two batches of keys:

$$\text{batchgcd}(i, j, k, l) = \text{gcd} \left(\prod_{m=i}^j n_m, \prod_{m=k}^l n_m \right)$$

If $\text{batchgcd}(i, j, k, l) \neq 1$ then one of keys n_i, \dots, n_j shares a factor with one of the keys n_k, \dots, n_l . (Note that you will want your two batches to be non-overlapping, since a key n_i always shares prime factors with itself. I.e., you should have $1 \leq i \leq j < k \leq l \leq t$.)

¹See N. Heninger, Z. Durumeric, E. Wustrow, and J.A. Halderman, "Mining Your Ps and Qs: Detection of Widespread Weak Keys in Network Devices," in *Proceedings of 21st USENIX Security Symposium*, 2012. <https://factorable.net>

Design a recursive algorithm that finds a pair of keys with a shared factor in your collection of t keys and analyze its runtime. Your algorithm may assume there is exactly one such pair. For full credit your algorithm should make $o(t^2)$ calls to `batchgcd`, which you can assume take constant time.

Solution:

```
def findKeysWithSharedFactor(A[a...b]):
    """The top-level invocation is findKeysWithSharedFactor(A[1...n])."""
    i = a; j = (b+a)/2; k=(b+a)/2+1; l = b
    if(len(A) == 1): # base case
        return []
    if(batchgcd(i,j,k,l) == 1):
        # The two bad keys are in the same half.
        # The recursive call with the largest input such that the two keys
        # are in separate halves proceeds to the while loops below;
        # all others eventually end up at the base case above.
        leftlist = findKeysWithSharedFactor(A[a...(b+a)/2])
        rightlist = findKeysWithSharedFactor(A[(b+a)/2+1...b])
        return leftlist.extend(rightlist)
    # One bad key in the left list and the other is in the right list.
    # Let's find the bad key in the left list.
    while(i != j):
        if(batchgcd(i,(i+j)/2,k,l) != 1): # Check left half of left list
            j = (i+j)/2
        else: # Check right half of left list
            i = (i+j)/2+1
    # Now let's find the bad key in the right list.
    leftbadkey = A[i]
    while(k != l):
        if(batchgcd(i,j,k,(k+l)/2) != 1): # Check left half of right list
            l = (k+l)/2
        else: # Check right half of right list
            k = (k+l)/2+1
    rightbadkey = A[k]
    return [leftbadkey, rightbadkey]
```

If the bad keys are in one half of the collection when splitting it down the middle, then the portion of the algorithm which looks for a common sublist obeys the recurrence $T(n) = 2T(n/2) + 2\Theta(1)$, which is order $\Theta(n \log n)$. Once our bad keys are in separate lists, we can then perform a binary search on each sublist individually, finding the bad key in the left list (keeping the right list constant) and then (with our left list reduced to just one bad key) finding the bad key in the right list. These two binary searches each take $\Theta(\log n)$ time. Hence the total runtime of the algorithm is $\Theta(n \log n) + 2\Theta(\log n) = \Theta(n \log n)$. ■

- (0) (d) (Not to submit.) Can you modify the algorithm to find all pairs of keys with a shared factor without the assumption that there is exactly one?
- (0) (e) (Not to submit.) Analyze the runtime of your algorithm if `batchgcd` takes logarithmic time in the size of the batches, i.e., $\Theta(\log(j - i) + \log(l - k))$?

Solved Problem

4. Suppose we are given two sets of n points, one set $\{p_1, p_2, \dots, p_n\}$ on the line $y = 0$ and the other set $\{q_1, q_2, \dots, q_n\}$ on the line $y = 1$. Consider the n line segments connecting each point p_i to the corresponding point q_i . Describe and analyze a divide-and-conquer algorithm to determine how many pairs of these line segments intersect, in $O(n \log n)$ time. See the example below.

Seven segments with endpoints on parallel lines, with 11 intersecting pairs.

Your input consists of two arrays $P[1..n]$ and $Q[1..n]$ of x -coordinates; you may assume that all $2n$ of these numbers are distinct. No proof of correctness is necessary, but you should justify the running time.

Solution: We begin by sorting the array $P[1..n]$ and permuting the array $Q[1..n]$ to maintain correspondence between endpoints, in $O(n \log n)$ time. Then for any indices $i < j$, segments i and j intersect if and only if $Q[i] > Q[j]$. Thus, our goal is to compute the number of pairs of indices $i < j$ such that $Q[i] > Q[j]$. Such a pair is called an *inversion*.

We count the number of inversions in Q using the following extension of mergesort; as a side effect, this algorithm also sorts Q . If $n < 100$, we use brute force in $O(1)$ time. Otherwise:

- Recursively count inversions in (and sort) $Q[1.. \lfloor n/2 \rfloor]$.
- Recursively count inversions in (and sort) $Q[\lfloor n/2 \rfloor + 1..n]$.
- Count inversions $Q[i] > Q[j]$ where $i \leq \lfloor n/2 \rfloor$ and $j > \lfloor n/2 \rfloor$ as follows:
 - Color the elements in the Left half $Q[1.. \lfloor n/2 \rfloor]$ **blue**.
 - Color the elements in the Right half $Q[\lfloor n/2 \rfloor + 1..n]$ **red**.
 - Merge $Q[1.. \lfloor n/2 \rfloor]$ and $Q[\lfloor n/2 \rfloor + 1..n]$, maintaining their colors.
 - For each **blue** element $Q[i]$, count the number of smaller **red** elements $Q[j]$.

The last substep can be performed in $O(n)$ time using a simple for-loop:

```

COUNTREDBLUE( $A[1..n]$ ):
  count  $\leftarrow$  0
  total  $\leftarrow$  0
  for  $i \leftarrow 1$  to  $n$ 
    if  $A[i]$  is red
      count  $\leftarrow$  count + 1
    else
      total  $\leftarrow$  total + count
  return total

```

In fact, we can execute the third merge-and-count step directly by modifying the MERGE algorithm, without any need for “colors”. Here changes to the standard MERGE algorithm are indicated in red.

```

MERGEANDCOUNT( $A[1..n], m$ ):
   $i \leftarrow 1; j \leftarrow m + 1; count \leftarrow 0; total \leftarrow 0$ 
  for  $k \leftarrow 1$  to  $n$ 
    if  $j > n$ 
       $B[k] \leftarrow A[i]; i \leftarrow i + 1; total \leftarrow total + count$ 
    else if  $i > m$ 
       $B[k] \leftarrow A[j]; j \leftarrow j + 1; count \leftarrow count + 1$ 
    else if  $A[i] < A[j]$ 
       $B[k] \leftarrow A[i]; i \leftarrow i + 1; total \leftarrow total + count$ 
    else
       $B[k] \leftarrow A[j]; j \leftarrow j + 1; count \leftarrow count + 1$ 
  for  $k \leftarrow 1$  to  $n$ 
     $A[k] \leftarrow B[k]$ 
  return  $total$ 

```

We can further optimize this algorithm by observing that $count$ is always equal to $j - m - 1$. (Proof: Initially, $j = m + 1$ and $count = 0$, and we always increment j and $count$ together.)

```

MERGEANDCOUNT2( $A[1..n], m$ ):
   $i \leftarrow 1; j \leftarrow m + 1; total \leftarrow 0$ 
  for  $k \leftarrow 1$  to  $n$ 
    if  $j > n$ 
       $B[k] \leftarrow A[i]; i \leftarrow i + 1; total \leftarrow total + j - m - 1$ 
    else if  $i > m$ 
       $B[k] \leftarrow A[j]; j \leftarrow j + 1$ 
    else if  $A[i] < A[j]$ 
       $B[k] \leftarrow A[i]; i \leftarrow i + 1; total \leftarrow total + j - m - 1$ 
    else
       $B[k] \leftarrow A[j]; j \leftarrow j + 1$ 
  for  $k \leftarrow 1$  to  $n$ 
     $A[k] \leftarrow B[k]$ 
  return  $total$ 

```

The modified MERGE algorithm still runs in $O(n)$ time, so the running time of the resulting modified mergesort still obeys the recurrence $T(n) = 2T(n/2) + O(n)$. We conclude that the overall running time is $O(n \log n)$, as required. ■

Rubric: 10 points = 2 for base case + 3 for divide (split and recurse) + 3 for conquer (merge and count) + 2 for time analysis. Max 3 points for a correct $O(n^2)$ -time algorithm. This is neither the only way to correctly describe this algorithm nor the only correct $O(n \log n)$ -time algorithm. No proof of correctness is required.
