## Binary Translation

## Binary Translation

- Emulation:
  - Guest code is traversed and instruction classes are mapped to routines that emulate them on the target architecture.
- Binary translation:
  - The entire program is translated into a binary of another architecture.
  - Each binary source instruction is emulated by some binary target instructions.

## Challenges

- Can we really just read the source binary and translate it statically one instruction at a time to a target binary?
  - What are some difficulties?

## Challenges

- Code discovery and dynamic translation
  - How to tell whether something is code or data?
  - Consider a jump instruction: Is the part that follows it code or data?
- Code location problem
  - How to map source program counter to target program counter (without having a table as long as the program for instruction-by-instruction mapping)?

## Things to Notice

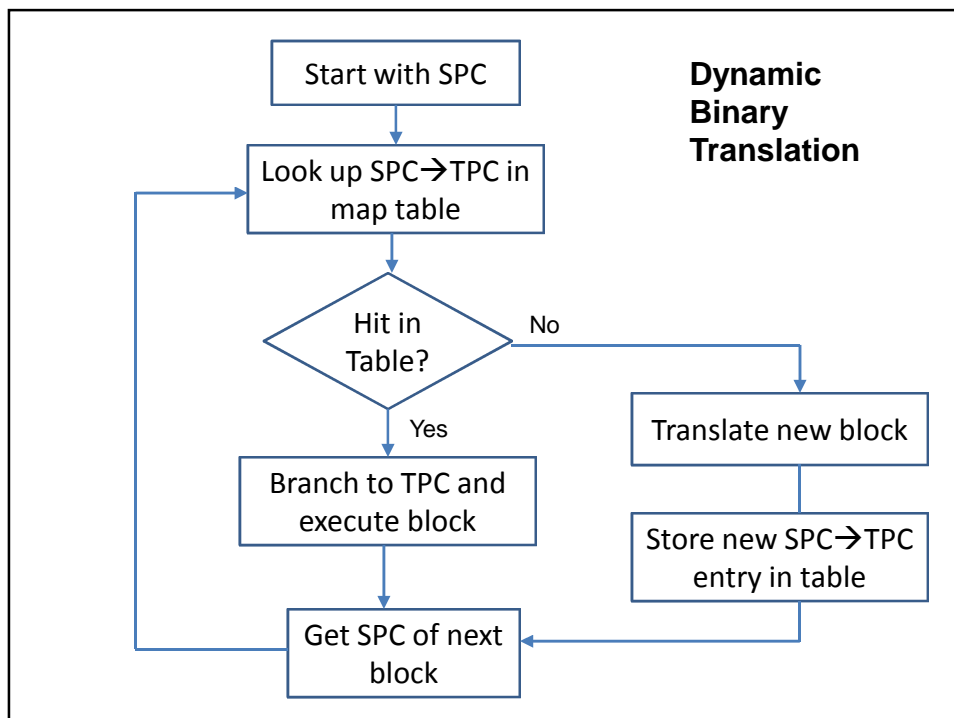

- You only need source-to-target program counter mapping for locations that are *targets of jumps*. Hence, only map those locations.
- You always know that something is an instruction (not data) in the source binary if the source program counter eventually ends up pointing to it.
- The problem is: You do not know targets of jumps (and what the program counter will end up pointing to) at static analysis time!
  - Why?

## Solution

- Incremental Pre-decoding and Translation
  - As you execute a source binary block, translate it into a target binary block (this way you know you are translating valid instructions)
  - Whenever you jump:
    - If you jump to a new location: start a new target binary block, record the mapping between source program counter and target program counter in map table.
    - If you jump to a location already in the map table, get the target program counter from the table
  - Jumps must go through an emulation manager. Blocks are translated (the first time only) then executed directly thereafter

## Dynamic Basic Blocks

- Program is translated into chunks called “dynamic basic blocks”, each composed of straight machine code of the target architecture
  - Block starts immediately after a jump instruction in the source binary
  - Block ends when a jump occurs
- At the end of each block (i.e., at jumps), emulation manager is called to inspect jump destination and transfer control to the right block with help of map table (or create a new block and map table entry, if map miss)

## Same ISA Emulation

- Why?

## Same ISA Emulation

- OS Emulation
  - Same machine architecture, different OS
  - Copy code as is, translate system calls.
- Replication
  - Copy code as is, except special instructions that deal with virtualized resources such as I/O.
  - Code running on Guest VMs (e.g., Guest OS code) cannot directly access these I/O resource.
- Program shepherding
  - Check that code does not execute something it is not supposed to (e.g., exploit security holes).

## Optimizations

- Translation chaining
  - The counterpart of threading in interpreters
  - The first time a jump is taken to a new destination, go through the emulation manager as usual
  - Subsequently, rather than going through the emulation manager at that jump (i.e., once destination block is known), just go to the right place.
    - What type of jumps can we do this with?

## Optimizations

- Translation chaining
  - The counterpart of threading in interpreters
  - The first time a jump is taken to a new destination, go through the emulation manager as usual
  - Subsequently, rather than going through the emulation manager at that jump (i.e., once destination block is known), just go to the right place.
    - What type of jumps can we do this with?
      - Fixed destination jumps!

## What about Register Indirect Jumps?

- Jump destination depends on value in register.
- Must search map table for destination value (expensive operation)
- Solution?

## What about Register Indirect Jumps?

- Jump destination depends on value in register.
- Must search map table for destination value (expensive operation)
- Solution
  - Caching: add a series of if statements, comparing register content to common jump source program counter values from past execution (most common first).
  - If there is a match, jump to corresponding target program counter location.
  - Else, go to emulation manager.
