The LPC-10 speech synthesis model

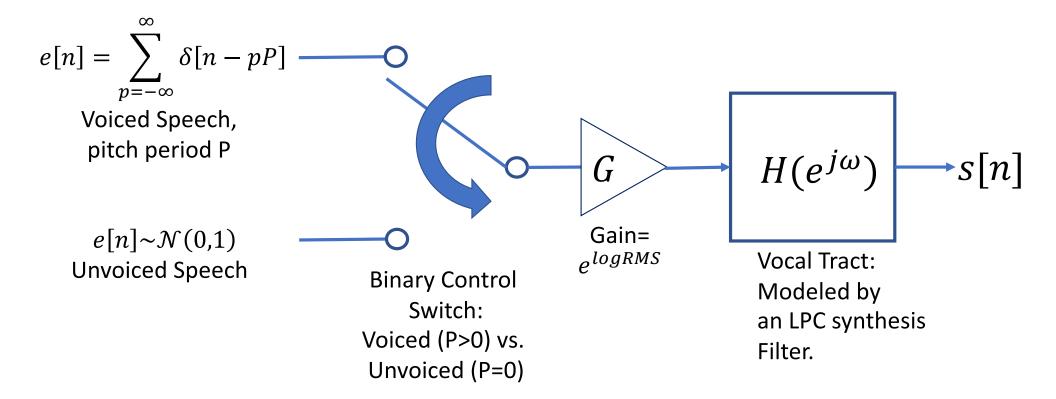

November 28, 1984

The LPC-10 Speech Coder: Transmitted Parameters

Each frame is 54 bits, and is used to synthesize 22.5ms of speech. (54 bits/frame)/(0.0225 seconds/frame)=2400 bits/second

- <u>**Pitch</u>**: 7 bits/frame (127 distinguishable non-zero pitch periods)</u>
- **Energy**: 5 bits/frame (32 levels, on a log-energy scale)
- 10 linear predictive coefficients (LPC): 41 bits/frame
- Synchronization: 1 bit/frame

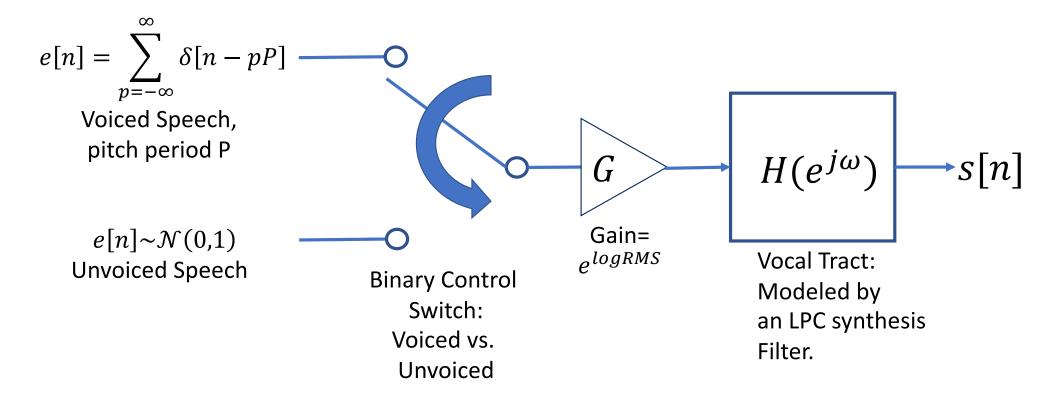

The LPC-10 speech synthesis model

Unvoiced speech: e[n]=white noise

- Use zero-mean, unit-variance Gaussian white noise
- The choice, to use "unvoiced speech," is communicated by the special code word "P=0"

By Morn - Own work, CC BY-SA 3.0, https://commons.wikimedia.org/w/index. php?curid=24084756

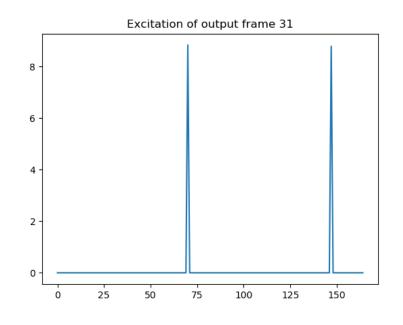

Voiced speech: e[n]=pulse train

• The basic idea: $_{\infty}$

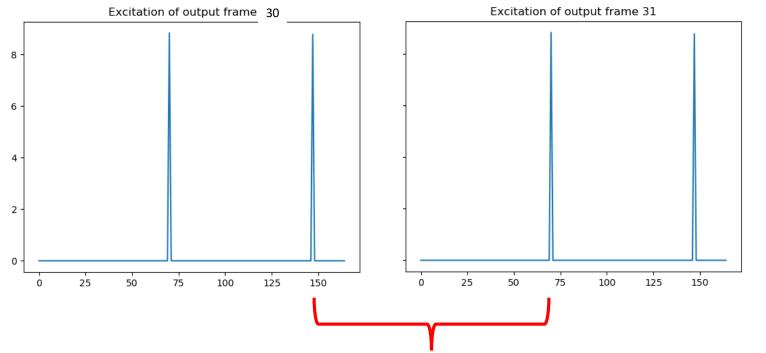

$$e[n] = \sum_{p = -\infty} \delta[n - pP]$$

• Modification #1: in order for the average energy to equal 1.0, we need to scale each pulse by \sqrt{P} :

$$e[n] = \sqrt{P} \sum_{p=-\infty}^{\infty} \delta[n - pP]$$

Modification #2: the first pulse is not at n=0

Pitch period = 80 samples \Rightarrow first pulse in frame 31 can't occur until the 70th sample of the frame

A mechanism for keeping track of pitch phase from one frame to the next

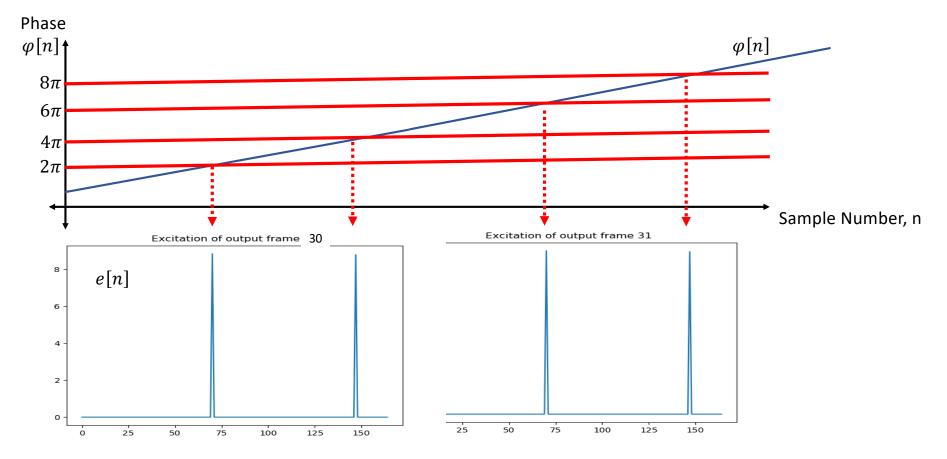

- Start out, at the beginning of the speech, with a pitch phase equal to zero, $\varphi[0]=0$
- For every sample thereafter:
 - If the sample is unvoiced (P[n]=0), don't increment the pitch phase
 - If the sample is voiced (P[n]>0), then increment the pitch phase

$$\varphi[n] = \varphi[n-1] + \frac{2\pi}{P[n]}$$

• Every time the phase passes a multiple of 2π , output a pitch pulse

$$e[n] = \begin{cases} \sqrt{P} & \left\lfloor \frac{\varphi[n]}{2\pi} \right\rfloor - \left\lfloor \frac{\varphi[n-1]}{2\pi} \right\rfloor > 0\\ 0 & else \end{cases}$$

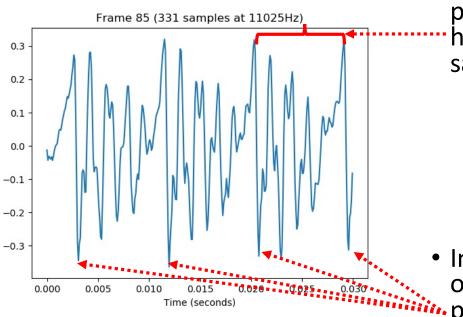

The pitch phase method: generate an excitation pulse whenever pitch phase crosses a 2π -level

Speech is predictable

 Speech is not just white noise and pulse train. In fact, each sample is
 highly predictable from previous samples.

$$x[n] \approx \sum_{m=1}^{10} a_m x[n-m]$$

 In fact, the pitch pulses are the only major exception to this
 predictability!

Linear predictive coding (LPC)

The LPC idea:

1. Model the excitation as error

$$e[n] = x[n] - \sum_{m=1}^{10} a_m x[n-m]$$

2. Force the coefficients α_m to explain as much as they can, so that e[n] is as close to zero as possible. Linear predictive coding (LPC)

$$\varepsilon = E[e^{2}[n]] = E\left[\left(x[n] - \sum_{i=1}^{10} a_{i}x[n-i]\right)^{2}\right]$$
$$\frac{\partial\varepsilon}{\partial\alpha_{j}} = -2E\left[x[n-j]\left(x[n] - \sum_{i=1}^{10} a_{i}x[n-i]\right)\right]$$

Setting
$$\frac{\partial \varepsilon}{\partial a_j} = 0$$
 gives

$$E[x[n-j]x[n]] = \sum_{i=1}^{10} a_i E[x[n-j]x[n-i]]$$

$$R_{xx}[j] = R_{xx}[i-j]$$

Linear predictive coding (LPC)

So we have a set of linked equations, for $1 \le j \le 10$:

$$R_{xx}[j] = \sum_{i=1}^{10} a_i R_{xx}[|i-j|]$$

- We can write these 10 equations as a 10x10 matrix equation: $\vec{\gamma} = R\vec{a}$
- ...which immediately gives the solution: $\vec{a} = R^{-1}\vec{\gamma}$
- ...where

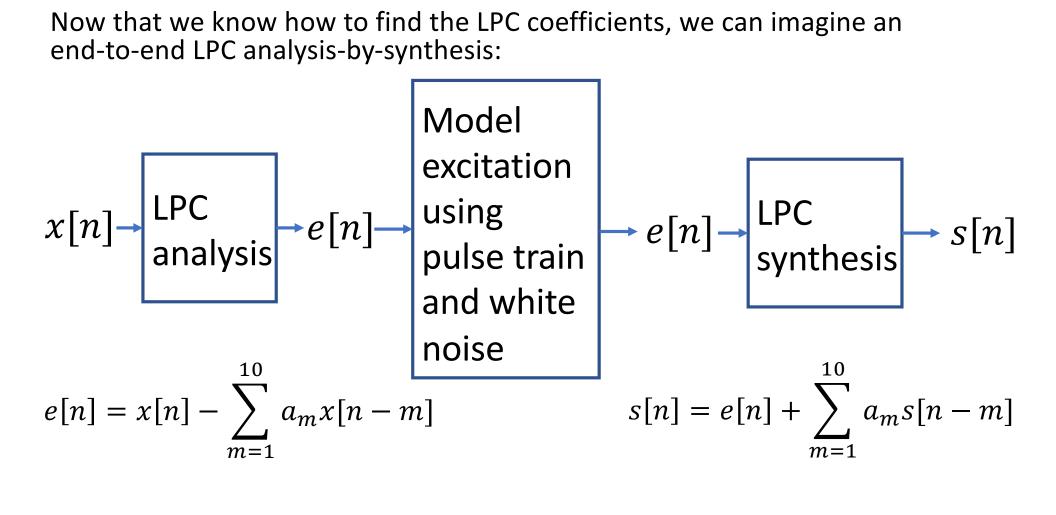

$$\vec{\gamma} = \begin{bmatrix} R_{xx}[1] \\ \vdots \\ R_{xx}[10] \end{bmatrix}, \quad R = \begin{bmatrix} R_{xx}[0] & R_{xx}[1] & \cdots \\ R_{xx}[1] & R_{xx}[0] & \cdots \\ \vdots & \vdots & R_{xx}[0] \end{bmatrix}, \quad \vec{a} = \begin{bmatrix} a_1 \\ \vdots \\ a_{10} \end{bmatrix}$$

Speech -> Excitation -> Speech

Now that we know how to find the LPC coefficients, we can imagine an

The LPC Analysis Filter

The LPC Analysis Filter is an all-zeros filter (FIR = finite impulse response):

$$e[n] = x[n] - \sum_{m=1}^{10} a_m x[n-m] \leftrightarrow E(z) = A(z)X(z)$$

...where...

$$A(z) = 1 - \sum_{m=1}^{10} a_m z^{-m}$$

The LPC Synthesis Filter

The LPC Synthesis Filter is an all-poles filter (IIR = infinite impulse response):

$$s[n] = e[n] + \sum_{m=1}^{10} a_m s[n-m] \leftrightarrow S(z) = H(z)E(z)$$

...where...

$$H(z) = \frac{1}{A(z)} = \frac{1}{1 - \sum_{m=1}^{10} a_m z^{-m}}$$

Speech -> Excitation -> Speech

$$x[n] \rightarrow A(z) \rightarrow e[n] \rightarrow$$
 Excitation
Model $\rightarrow e[n] \rightarrow e[n] \rightarrow \frac{1}{A(z)} \rightarrow s[n]$

The Stability Problem

- The analysis filter is guaranteed to be stable, as long as the coefficients are finite. Suppose you know that $|x[n]| \le X_{MAX}$, and $|\alpha_m| \le \alpha_{MAX}$. Then, even in the worst possible case, $|e[n]| \le 11\alpha_{MAX}X_{MAX}$.
- The synthesis filter has no such guarantee. For example, suppose e[n] is just a delta function ($e[n] = \delta[n]$), and suppose all of the $\alpha_m = 0$ except the first one, $\alpha_1 = 1.1$. Then

$$s[n] = \delta[n] + 1.1s[n-1] = (1.1)^n$$

Which overflows your 16-bit sample buffer after only 110 samples. Your output will be full of NaNs, and you'll be saying "What happened...?"

How to Guarantee Stability

Fortunately, the LPC synthesis filter is causal, so it's easy to guarantee stability. We just need to make sure that all of the poles have magnitude less than 1:

 $|r_k| < 1$

We find the poles like this:

$$H(z) = \frac{1}{A(z)} = \frac{1}{1 - \sum_{m=1}^{10} a_m z^{-m}} = \frac{1}{\prod_{k=1}^{10} (1 - p_k z^{-1})}$$

in other words,

$$p_k = roots(A(z))$$

...which you can do using np.roots, if you define the polynomial correctly. Then you just truncate the magnitude,

$$p_k \leftarrow \min(|p_k|, 0.999)e^{j \measuredangle p_k}$$

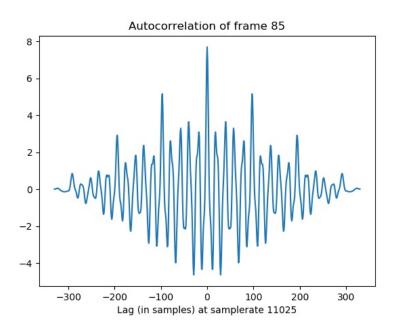

...and then use np.poly to convert back from roots to polynomial.

Outline

- The LPC-10 speech synthesis model
- The LPC-10 excitation model: white noise, pulse train
- Linear predictive coding: how to find the coefficients
- Linear predictive coding: how to make sure the coefficients are stable
- Autocorrelation-based pitch tracking
- Inter-frame interpolation of pitch and energy contours

Autocorrelation is maximum at n=0

$$R_{xx}[n] = \sum_{m=-\infty}^{\infty} x[m]x[m-n]$$

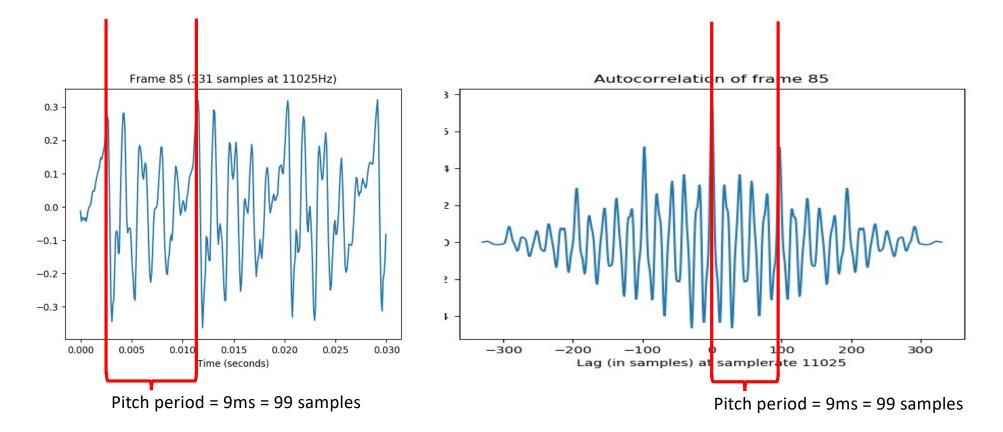

Autocorrelation of a periodic signal

Suppose x[n] is periodic, x[n] = x[n - P]. Then the autocorrelation is also periodic:

$$R_{xx}[P] = \sum_{m=-\infty}^{\infty} x[m]x[m-P] = \sum_{m=-\infty}^{\infty} x^{2}[m] = r_{xx}[0]$$

Autocorrelation of a periodic signal is periodic

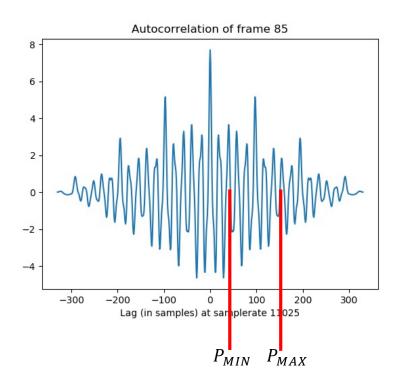

Autocorrelation pitch tracking

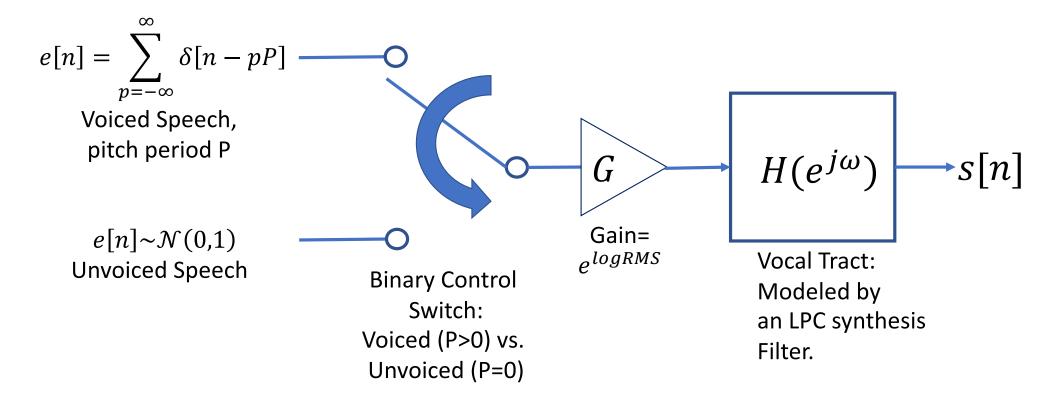

- Compute the autocorrelation
- Find the pitch period:

 $P = \operatorname*{argmax}_{P_{MIN} \le m \le P_{MAX}} R_{xx}[m]$

- The search limits, P_{MIN} and P_{MAX} , are important for good performance:
 - P_{MIN} corresponds to a high woman's pitch, about $F_S/P_{MIN} \approx 250$ Hz
 - P_{MAX} corresponds to a low man's pitch, about $F_S/P_{MAX} \approx 80$ Hz

The LPC-10 speech synthesis model

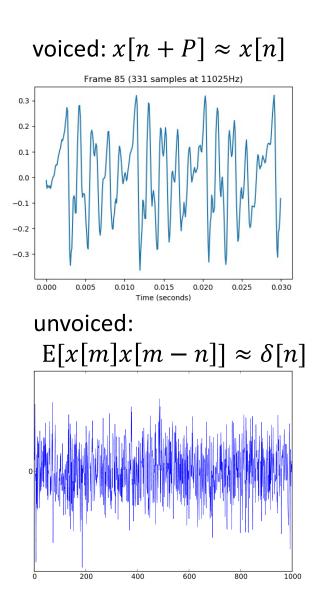

The voiced/unvoiced decision

- x[n] voiced: $r_{xx}[P] \approx r_{xx}[0]$
- x[n] unvoiced (white noise): $r_{xx}[n] \approx \delta[n]$ which means that $r_{xx}[P] \ll r_{xx}[0]$

So a reasonable V/UV decision is:

- $\frac{r_{xx}[P]}{r_{xx}[0]} \ge threshold$: say the frame is voiced.
- $\frac{r_{xx}[P]}{r_{xx}[0]} < threshold$: say the frame is unvoiced.

Setting threshold~0.25 works reasonably well.

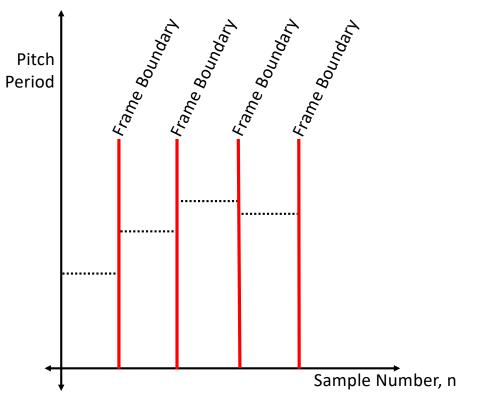

Outline

- The LPC-10 speech synthesis model
- The LPC-10 excitation model: white noise, pulse train
- Linear predictive coding: how to find the coefficients
- Linear predictive coding: how to make sure the coefficients are stable
- Autocorrelation-based pitch tracking
- Inter-frame interpolation of pitch and energy contours

Inter-frame interpolation of pitch contours

We don't want the pitch period to change suddenly at frame boundaries; it sounds weird.

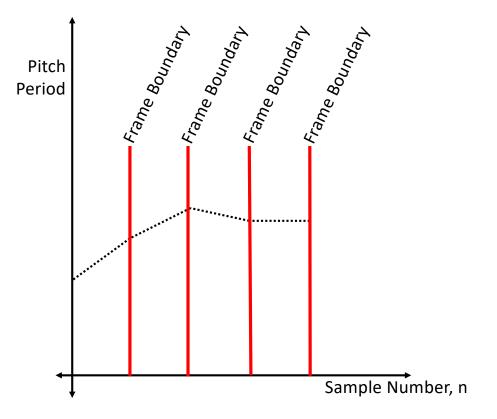

Inter-frame interpolation of pitch contours

Linear interpolation sounds much better. We can accomplish linear interpolation using a formula like

$$P[n] = (1 - f)P_t + fP_{t+1}$$

Where

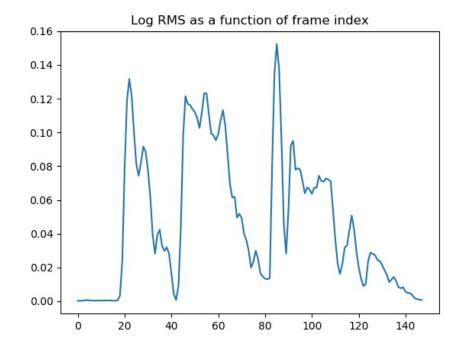

- P_t is the pitch period in frame t
- $f = \frac{n-tS}{S}$ is how far sample n is from the beginning of frame t
- S is the frame-skip.

Inter-frame interpolation of energy

Linear interpolation is also useful for energy, EXCEPT: it sounds better if we interpolate log energy, not energy.

$$\log RMS_t = \log \sqrt{\frac{1}{L} \sum_{n=tS}^{tS+L-1} x^2[n]}$$

The LPC-10 Speech Synthesis Model

• Excitation:

- Unvoiced speech: $e[n] \sim \mathcal{N}(0,1)$
- Voiced speech: $e[n] = \sqrt{P} \sum_{p=-\infty}^{\infty} \delta[n pP]$
- Linear prediction: $s[n] = e[n] + \sum_{m=1}^{10} a_m s[n-m]$
 - Minimizing $E[e^2[n]]$ yields the equations $\vec{\gamma} = R\vec{a}$, where

$$\vec{\gamma} = \begin{bmatrix} R_{xx}[1] \\ \vdots \\ R_{xx}[10] \end{bmatrix}, \qquad R = \begin{bmatrix} R_{xx}[0] & R_{xx}[1] & \cdots \\ R_{xx}[1] & R_{xx}[0] & \cdots \\ \vdots & \vdots & R_{xx}[0] \end{bmatrix}, \qquad \vec{a} = \begin{bmatrix} a_1 \\ \vdots \\ a_{10} \end{bmatrix}$$

- Stability: make sure $|p_k| < 1$
- Pitch tracking: $P = \underset{P_{MIN} \le m \le P_{MAX}}{\operatorname{argmax}} R_{xx}[m]$
